

On the premelting features in sodium clusters

F. Calvo and F. Spiegelman

Melting in Na_n clusters described with an empirical embedded-atom potential has been reexamined in the size range $55 \leq n \leq 147$ with a special attention at sizes close to 130. Contrary to previous findings, premelting effects are also present at such medium sizes, and they turn out to be even stronger than the melting process itself for Na_{133} or Na_{135} . These results indicate that the empirical potential is *qualitatively* inadequate to model sodium clusters.

Introduction

The early days of cluster thermodynamics were first mostly concerned with theoretical or numerical studies of simple rare-gas aggregates. Beyond the now generally accepted idea that melting in finite atomic clusters appears as a first-order transition rounded by size effects,¹ it was also observed in simulations that these system can exhibit dynamical coexistence,² a process in which the cluster fluctuates in time between its solidlike and liquidlike states.

While no experiment has yet permitted to test these predictions on the very same clusters, recent observations achieved in the group lead by Haberland^{3,4,5} have provided valuable qualitative and quantitative information about the way sodium clusters melt, by extracting the full caloric curves from photodissociation measurements. In particular these authors reported that the melting point and the latent heat of fusion both vary strongly and non-monotonically with size.⁴ These results significantly attracted the attention of theoreticians, who since then tried to interpret or reproduce these unexpected complex variations using a variety of models.^{6,7,8,9,10,11,12} Further evidence was also sought in indicators, which are alternative to the caloric curves, such as the electric polarizability,¹³ the photoabsorption spectrum,¹⁴ or the ionization potential.¹¹

Up to now, none of the above cited theoretical works has been able to reach a fully satisfactory quantitative agreement with experiments. The situation is largely due to the expected strong interplay between geometric and electronic effects, which could be responsible for the variations of the thermodynamic quantities. However, the previous simulations have brought some clues about the relevance of the various models and potentials used to describe simple metal clusters. For instance, it was seen that the distance dependent tight-binding (TB) model developed by Poteau and Spiegelman¹⁵ overestimated melting points by more than 20 percents. This was interpreted as the consequence of the parameterization of this model, carried out on small clusters only but not on bulk properties.⁷ On the other hand, both the empirical embedded-atom model (EAM) potential^{6,7,11,12} and orbital-free density functional⁹ calculations lead to a notable underestimation. Unfortunately, more realistic simulations still lack the extent of phase space sampling

required for a precise computation of the melting point above 50 atoms.

Numerical experiments

In our previous works, we concluded that melting in sodium clusters actually occurs differently in the smallest and in medium to large sizes clusters.^{6,7} While the caloric curve of the smallest clusters (having less than about 80 atoms) exhibit several features due to multiple isomerizations prior melting, the heat capacity of the larger sizes mainly has one main peak indicating melting in a non ambiguous way. This could partly explain why experimental measurements do not find such premelting features above 55 atoms, and also why they have difficulties in getting a clear, single-peak picture below this size. More recently we noticed that premelting effects could also be artefactually due to poorly converged simulations.⁸

Based on our previous results, the disagreement between experimental measurements and the results of both the TB and EAM models seemed mostly quantitative. One could hope in getting a much better agreement by suitably modifying the parameters, after including both molecular and bulk properties, possibly through allowing these parameters to become size-dependent. However, the range of sizes that was investigated by us and by others was quite limited,^{6,7,11,12} with only very few sizes above 80. Moreover, the mediocre agreement for the latent heats of fusion lead us revisit the problem with newly available simulation methods and less ambiguous tools of analysis.

We have performed exchange Monte Carlo canonical simulations¹⁶ of the clusters Na_n with $55 \leq n \leq 145$, n being a multiple of 5 in this range, plus the following sizes $n = 59, 93, 127, 129\text{--}131, 133, 139, 142$, and 147. The clusters are again described using the same empirical many-body EAM potential whose parameters are given in Ref. 17, and each simulation consisted of 10^7 cycles following 2×10^6 equilibration cycles for each of the 31 trajectories characterized by their temperature $T_i = i \times 10$ K for $1 \leq i \leq 30$ plus $i = 1.5$. The starting structures for all clusters was always chosen to be the result of basin-hopping global optimization carried out with 10 sets of 10^4 quenches. All were found to be based on the icosahed-

dral motif. The absence of any different structural motif such as octahedral or decahedral for the sizes studied here is very favorable for the simulations to reach equilibrium and not fall into broken ergodicity problems, as one major cause for such difficulties precisely lies in the energy landscape having several funnels.^{18,19} Each cluster was simulated 5 times independently, with different random seeds, and we used a hard-wall spherical container with radius $R_{\max} = 7n^{1/3}$. The caloric curves were constructed from the distributions of potential energies using a multihistogram technique. In Ref. 7, we calculated the latent heat of melting, L , as the integral of the heat capacity minus the Dulong-Petit contribution. This lead to appreciable overestimates, mostly due to the neglect of anharmonicities. Here we proceed similarly to the experimental approach of Schmidt and coworkers,⁴ namely by fitting the low- and high-temperature parts of the internal energy as straight lines and defining L as the gap between these lines at the melting point T_{melt} . The melting point itself is defined as the temperature at which the *last* heat capacity peak has its maximum: in cases where there are several peaks each centered around $T_{\text{melt}}^{(k)}$ the true melting temperature is taken as $\max_k \{T_{\text{melt}}^{(k)}\}$. The low- and high-temperature parts are defined as $T \leq 50$ K and $T \geq 250$ K, respectively. Therefore, if premelting events are present between these limits, they will contribute to the latent heat.

Results and discussion

FIG. 1: Melting point T_{melt} and latent heat of melting L of sodium cluster clusters versus their size. The open squares are the experimental results of Schmidt *et al.*⁵, the full circles are for Monte Carlo simulations using the empirical potential.

The variations of T_{melt} and L with size are sketched in Fig. 1 along with the latest experimental data of Schmidt

and coworkers.⁵ Except for very low sizes, we first notice that the melting points computed here are significantly lower than the ones we previously reported.⁷ This is an unfortunate consequence of using the q-jumping method with an inappropriate Tsallis parameter.²⁰ However they are comparable to the ones obtained by Garzón and coworkers in the microcanonical ensemble.¹² Since we expect the differences between this ensemble and the canonical ensemble to become smaller and smaller for increasing sizes, this agreement appear as a mutual confirmation of the convergence of both calculations, even though they rely on very different numerical experiments.

Interestingly, the experimental and theoretical variations of T_{melt} with size appear to be related to each other, especially if we shift the simulation data around size 120 by about 15 atoms and 70 K. This had not been noticed before, and is probably fortuitous. But it may also hide that some mechanisms causing the strong variations in the experimental results close to 140 atoms are indeed the same here, only occurring sooner.

In Fig. 1 one should also notice that the melting point at $n = 55$ is not the highest, as clusters having 59 or 60 atoms are more resistant to an increase in temperature. However, we were not able to extract any latent heat for these sizes (nor for $n = 65$ and 70) due to very broad heat capacity peaks. Therefore one should maybe not give too much importance to the melting points extracted from these curves.

While the melting temperatures are usually well below the experimental data (except in the vicinity of 130 atoms), the computed latent heats show a reasonable overall agreement, even though the complex variations are not as sharply seen as in the measurements of Schmidt *et al.*⁸ A definitive comparison would require one to extend the range of sizes. As far as latent heats are concerned, the difference between the present results and our previously published data⁷ comes nearly entirely from the different way of estimating L , which is now much closer to the experimental way.

The heat capacity curves in the range $125 \leq n \leq 135$ are all plotted in Fig. 2 versus temperature. Despite strong changes from one size to another, a regular evolution can be seen from 125 atoms and above this size. The heat capacity consists of two peaks, the melting (or high-temperature) peak being centered near 203 K. The smaller peak, denoted as premelting peak in the following, goes from 100 to about 180 K in a quite continuous fashion. The premelting peak is surprisingly strong, and can be clearly distinguished from the melting peak. Strikingly, it is even stronger than the melting peak itself at size 133.

To interpret these curves, we have chosen to focus on Na_{133} , by carrying periodic quenches from instantaneous configurations extracted from the Monte Carlo simulations for all trajectories. We thus gathered nearly 14000 different isomers. Fig. 3 shows the energy of these isomers versus their rank, as well as the discrete spectrum of isomers versus the temperature of the trajectory from

FIG. 2: Heat capacities of sodium clusters calculated with exchange Monte Carlo using the empirical potential, in the size range $125 \leq n \leq 135$. The inset shows the curve obtained for Na_{133} using the tight-binding quantum model.

which they were quenched. Both graphs clearly indicate a correlation between the repartition of isomers in energy space, their number and the heat capacities. Small variations in C_v occur below 150 K, but are hardly visible when compared to the main peaks. They are related to the first few hundreds of isomers, which involve the migration of a limited number of some of the missing atoms on the external layer of the icosahedron (the 135-atom cluster has I_h symmetry with all vertex atoms missing).

The presence of two major peaks in C_v is consistent with the two main increases in the number of isomers having less than a given energy. Most new isomers appearing between 150 and 190 K have their rank between 1000 and 5000 in the upper part of Fig. 3. Looking at their structure reveals that they are all still based on the two-layer icosahedron, but that the third layer is hardly recognisable. Hence this case of premelting is an extreme illustration of surface melting following preliminar surface reconstruction.²¹ Eventually, above 200 K the icosahedral structure is completely lost and the true (volume) melting takes place.

If now we look more closely at the results obtained for Na_{135} , we notice that the main peak is indeed located at the same temperature as the premelting peak in Na_{133} , and that the true melting peak of the latter cluster has been replaced by a right shoulder. Thus the same phenomena seem to be present in Na_{135} , only with different relative magnitude. This case could be referred to as 'post-melting'.

To some extent, this progressive evolution of the premelting and melting peaks can be compared to what has been observed in small Lennard-Jones (LJ) clusters by Frantz.²² In these systems, a premelting peak starts ap-

FIG. 3: Quenching analysis of the Monte Carlo trajectories for Na_{133} . Lower panel: spectra of isomers versus temperature. Upper panel: energy versus isomer rank.

pearing close to the size 31 corresponding to the competition between Mackay-type and anti-Mackay-type icosahedral structures. The premelting peak remains as the cluster size increases, and it is shifted to higher temperatures before becoming higher than the melting peak itself near the size 38.²² Because of the structural similarities between LJ clusters and the present sodium clusters, it is likely that the present observations express the same qualitative mechanisms. However, a significant quantitative difference can be seen in the caloric curves of LJ clusters and sodium clusters, as the melting peak is never really well resolved for van der Waals systems until it has replaced the premelting peak. Here the two peaks are of very similar widths, but their respective heights vary strongly, their total contribution to the latent heat being nearly constant.

Up to now, experimental data did not find any evidence for any pronounced premelting peak in the heat capacities of charged sodium clusters.^{3,4,5} This indicates that the present empirical potential is *qualitatively* inadequate to describe these systems. In particular, beyond a simple scaling of the parameters of the potential, we do not expect the use of explicit, size-dependent parameters to improve the situation notably. We repeated the above simulation for Na_{133} using the more realistic quantum distance-dependent tight-binding (TB) Hamiltonian described in Ref. 15, but we had to reduce the statistics

to 10^6 cycles following 2×10^5 equilibration cycles (per trajectory) for the computation to be tractable. Even though melting points were shown to be overestimated,⁷ we also noticed⁸ that premelting effects were quite reduced using this model, in better consistency with experiments. The heat capacity computed from exchange Monte Carlo simulations is reported in the inset of Fig. 2. For this calculation we neglected the (weak) effects of nonzero electronic temperature.⁸ The starting configuration was taken as the same one as for the classical potential, but we did not find any more stable structure during the course of the simulation.

At first sight, the caloric curve looks similar to the classical result, with a clear premelting peak. However using the TB Hamiltonian has two consequences. First, the premelting peak is much lower than the melting peak, which is in agreement with our previous general observation that the empirical potential overemphasizes premelting features.^{7,8} More importantly, premelting also occurs much closer in temperature to the melting peak itself. This also suggest that premelting is not seen experimentally simply because it is too broad.

Conclusion

In the present work, we have obtained some evidence that premelting effects in the caloric curves of sodium clusters could be present at unexpectedly large sizes. We also found that some clusters could exhibit 'post-melting', a process in which the premelting effect is stronger than the actual melting peak. In the cases stud-

ied here, these effects seem to be associated with surface reconstruction of the third icosahedral layer, and thus seem to be of character similar to what occurs in Lennard-Jones clusters having about 35 atoms.²²

One consequence of the above results is that explicit empirical potentials are not fully reliable for predicting melting points in small sodium clusters, not only because they do not allow one to reproduce the complex variations observed by the group of Haberland,⁴ but mostly because they exhibit prominent premelting peaks not seen in experiments.

Calculations performed using the quantum tight-binding model also predict a premelting phenomenon near 133 atoms, but the corresponding anomaly of the heat capacity is much smaller than the melting peak, as well as closer to it. In this respect, it resembles more the measurements by Schmidt *et al.*⁴

Even though our calculations overestimate premelting effects, they provide insight into the possible causes for the nonmonotonic variations of the melting point. In particular, they suggest that such variations may reflect premelting becoming actual melting. The discrepancies with the present work would then be ascribed to a possible merging of the premelting feature into one shoulder of the melting peak, but not necessarily on the low temperature side.

Acknowledgments

The authors wish to thank H. Haberland for helpful discussions.
